ABSTRACT

Cloud computing offers a new, attractive option to customers for quickly provisioning any size Hadoop cluster, consuming resources as a service, executing their MapReduce workload, and then paying for the time these resources were used. One of the open questions in such environments is the right choice of resources (and their amount) a user should lease from the service provider. Typically, there is a variety of different types of VM instances in the Cloud (e.g., small, medium, or large EC2 instances). The capacity differences of the offered VMs are reflected in VM’s pricing. Therefore, for the same price a user can get a variety of Hadoop clusters based on different VM instance types. We observe that the performance of MapReduce applications may vary significantly on different platforms. This makes a selection of the best cost/performance platform for a given workload a non-trivial problem, especially when it contains multiple jobs with different platform preferences. We aim to solve the following problem: given a completion time target for a set of MapReduce jobs, determine a homogeneous or heterogeneous Hadoop cluster configuration (i.e., the number, types of VMs, and the job schedule) for processing these jobs within a given deadline while minimizing the rented infrastructure cost. In this work, we design an efficient and fast simulation-based framework for evaluating and selecting the right underlying platform for achieving the desirable Service Level Objectives (SLOs). Our evaluation study with Amazon EC2 platform reveals that for different workload mixes, an optimized platform choice may result in 45-68% cost savings for achieving the same performance objectives when using different (but seemingly equivalent) choices. Moreover, depending on a workload the heterogeneous solution may outperform the homogeneous cluster solution by 26-42%. We provide additional insights explaining the obtained results by profiling the performance characteristics of used applications and underlying EC2 platforms. The results of our simulation study are validated through experiments with Hadoop clusters deployed on different Amazon EC2 instances.

1. INTRODUCTION

Cloud computing offers a new delivery model with virtually unlimited computing and storage resources. This is an attractive option for many users because acquiring, setting up, and maintaining a complex, large-scale infrastructure such as a Hadoop cluster requires a significant up-front investment in the new infrastructure, training new personnel, and then a continuous maintenance and management support, that can be difficult to justify. Cloud computing offers a compelling, cost-efficient approach that allows users to rent resources in a “pay-per-use” manner. For many users this creates an attractive and affordable alternative compared to acquiring and maintaining their own infrastructure.

A typical cloud environment provides a selection of different capacity Virtual Machines for deployment at different prices per time unit. For example, the Amazon EC2 platform offers a choice of small, medium, and large VM instances (among the other choices), where the CPU and RAM capacity of a medium VM instance is two times larger than the capacity of a small VM instance, and the CPU and RAM capacity of a large VM instance is two times larger than the capacity of a medium VM instance. This resource difference is also reflected in the price: the large instance is twice (four times) more expensive compared with the medium (small) VM instance. Therefore, a user is facing a variety of platform and configuration choices that can be obtained for the same cost.

To demonstrate the challenges in making an optimized platform choice we performed a set of experiments with two popular applications TeraSort and KMeans on three Hadoop clusters, deployed with different type VM instances:

- 40 small VMs, each configured with 1 map and 1 reduce slot;
- 20 medium VMs, each configured with 2 map and 2 reduce slots, and
- 10 large VMs, each configured with 4 map and 4 reduce slots.

Therefore, the three Hadoop clusters can be obtained for the same price per time unit, and they have the same number of map and reduce slots for processing (where each slot is provisioned with the same CPU and RAM capacities). Figure 2 shows the summary of our experiments with TeraSort and KMeans.

![Figure 1: Normalized completion time of two applications executed on different types of EC2 instances.](image)

Apparently, the Hadoop cluster with 40 small VMs provides the best completion time for a TeraSort application as shown in Fig-
Figure 1 (a). The completion time of TeraSort on the cluster with small VMs is 5.5 (2.3) times better, i.e., smaller, than on the cluster with large (medium) VMs. Since the cost of all three clusters per time unit is the same, the shortest completion time results in the lowest monetary cost the customer should pay. Therefore, the Hadoop cluster with 40 small VMs offers the best solution for TeraSort. By contrast, the Hadoop cluster with 10 large VMs is the best option for KMeans as shown in Figure 1 (b). It outperforms the Hadoop cluster with small VMs by 2.6 times when processing KMeans. This experiment demonstrates that seemingly equivalent platform choices for a Hadoop cluster in the Cloud might result in a different application performance that could lead to a different provisioning cost.

The problem of optimized platform choice becomes even more complex when a given workload contains multiple jobs with different performance preferences. Intuitively, if performance of jobs in the set would benefit from the small VMs (or large VMs) then the platform choice for a corresponding Hadoop cluster is relatively straightforward. However, if a given set of jobs has the applications with different performance preferences, then a platform choice becomes non-trivial. Figure 2 shows completion times (absolute, not normalized) of TeraSort and KMeans on three Hadoop clusters deployed with different type VM instances (these graphs resemble the normalized results shown in Figure 1). Apparently, when making a decision on the best platform for a Hadoop cluster to execute both of these applications (as a set) in the most cost effective way, one needs to look at the reduction of absolute execution times due to the choice of a common underlying platform.

Figure 2: Completion time of two applications executed on different types of EC2 instances.

Apparently, the absolute time benefits from processing KMeans on the large VMs significantly overweight the benefits of processing TeraSort on the small VMs.

In this work, we aim to solve the problem of the platform choice to provide the best cost/performance trade-offs for a given MapReduce workload and the Hadoop cluster. As shown in Figures 1, 2 this choice is non-trivial and depends on the application characteristics. The problem is even more difficult when the performance objective is to minimize the makespan (the overall completion time) of a given job set. In this work, we first offer a framework for solving the following two problems. Given a workload, select the type and size of the underlying platform for a homogeneous Hadoop cluster that provides best cost/performance trade-offs: i) minimizing the cost (budget) while achieving a given makespan target, or ii) minimizing the achievable jobs makespan for a given budget.

We also observe that a user might have additional considerations for a case with node failure(s). Hadoop is designed to support fault-tolerance, i.e., it will finish job processing even in the case of a node failure by using the remaining resources and restarting/recomputing failed tasks. However, if the cluster is based on 40 small VM instances then a single node failure leads to a loss of 2.5% of the overall resources, and it impacts only a limited number of map and reduce tasks. While in the cluster based on 10 large VM instances, a single node failure leads to a loss of 10% of the overall resources and a much higher number of impacted map and reduce tasks. We provide an extension of the proposed framework for selecting and sizing a Hadoop cluster to support the job performance objectives in case of node failure(s) in the cluster.

In our earlier work [22], we discussed a framework for the optimized platform selection of a single homogeneous Hadoop cluster. However, a heterogeneous cluster might not always present the best solution. Intuitively, if a given set of jobs has the applications with different platform preferences then a heterogeneous solution (that combines Hadoop clusters deployed with different instance types) might be a better choice. To support the choice of the heterogeneous solution, we introduce an application preference ranking to reflect the “strength” of application preference between different VM types and the possible impact on the provisioning cost (see our discussion related to the absolute completion times of KMeans and TeraSort shown in Figure 2). This preference ranking guides the construction of a heterogeneous solution. In the designed simulation-based framework, we collect jobs’ profiles from a given set, create an optimized job schedule that minimizes jobs’ makespan (as a function of job profiles and a cluster size), and then obtain the accurate estimates of the achievable makespan by replaying jobs’ traces in the simulator. Based on the cost of the best homogeneous Hadoop cluster, we provide a quick walk through a set of heterogeneous solutions (and corresponding jobs’ partitioning into different pools) to see whether there is a heterogeneous solution that can process given jobs within a deadline but at a smaller cost.

In our performance study, we use a set of 13 diverse MapReduce applications for creating three different workloads. Our experiments with Amazon EC2 platform reveal that for different workloads, an optimized platform choice may result in up to 45%-68% cost savings for achieving the same performance objectives when using different (but seemingly equivalent) choices. Moreover, depending on a workload the heterogeneous solution may outperform the homogeneous one by 26-42%. The results of our simulation study are validated through experiments with Hadoop clusters deployed on different Amazon EC2 instances.

The rest of the paper is organized as follows. Section 2 outlines our approach and explain details of the building blocks used in our solution. Section 3 described the general problem definition (two separate cases) for the homogeneous cluster case and outlines both solutions. Section 4 outlines the extension of the proposed framework for a case with node failure(s). Section 5 motivates the heterogeneous clusters solution and provides the corresponding provisioning algorithm. Section 6 presents the evaluation study by comparing the effectiveness of the proposed algorithms and their outcomes for different workloads. Section 7 outlines related work. Section 8 summarizes our contribution and gives directions for future work.

2. BUILDING BLOCKS

In this section, we outline our approach and explain details of the following building blocks used in our solution: i) collected job traces and job profiles; ii) an optimized job schedule to minimize the jobs’ execution makespan; iii) the MapReduce simulator to replay the job traces according to the generated job schedule for obtaining the accurate estimates of jobs performance and cost values.

1) Job Traces and Profiles: In summary, the MapReduce job execution is comprised of two stages: map stage and reduce stage. The map stage is partitioned into map tasks and the reduce stage is partitioned into reduce tasks, and they are distributed and executed across multiple machines.

Each map task processes a logical split of the input data that generally resides on a distributed file system. The map task applies the user-defined map function on each record and buffers the resulting output. This intermediate data is hash-partitioned for the different
reduce tasks and written to the local hard disk of the worker executing the map task.

We use the past job run(s) for creating the job traces that contain recorded durations of all processed map and reduce tasks\(^4\). A similar job trace can be extracted from the Hadoop job tracker logs using tools such as Rumor [11]. The obtained map/reduce task distributions can be used for extracting the distribution parameters and generating scaled traces, i.e., generating the replayable traces of the job execution on the large dataset from the sample job execution on the smaller dataset as described in [13]. These job traces can be replayed using a MapReduce simulator [12] and used for creating the compact job profile for analytic models.

For predicting the job completion time we use a compact job profile that characterize the job execution during map, shuffle, and reduce phases via average and maximum task durations. The proposed MapReduce performance model [14] evaluates lower bounds \(T^\text{low}\) and upper bounds \(T^\text{up}\) on the job completion time. It is based the Makespan Theorem [13] for computing performance bounds on the completion time of a given set of \(n\) tasks that are processed by \(k\) servers, (e.g., \(n\) map tasks are processed by \(k\) map slots in MapReduce environment), the completion time of the entire \(n\) tasks is proven to be at least:

\[
T^\text{low} = \text{avg} \cdot \frac{n}{k}
\]

and at most

\[
T^\text{up} = \text{avg} \cdot \frac{(n-1)}{k} + \text{max}
\]

The difference between lower and upper bounds represents the range of possible completion times due to task scheduling non-determinism. As was shown in [14], the average of lower and upper bounds (\(T^\text{avg}\)) is a good approximation of the job completion time (typically, it is within 10%). Using this approach, we can estimate the duration of map and reduce stages of a given job as a function of allocated resources (i.e., on different size Hadoop clusters). In particular, we apply this analytic model in the process of building an optimized job schedule to minimize the overall jobs’ execution time.

2) An Optimized Job Schedule: It was observed [15, 21] that for a set of MapReduce jobs (with no data dependencies between them) the order in which jobs are executed might have a significant impact on the jobs makespan, i.e., jobs overall completion time, and therefore, on the cost of the rented Hadoop cluster. For data-independent jobs, once the first job completes its map stage and begins the reduce stage, the next job can start executing its map stage with the released map resources in a pipelined fashion. There is an “overlap” in executions of map stage of the next job and the reduce stage of the previous one. As an illustration, let us consider two MapReduce jobs that have the following map and reduce stage durations:

- Job \(J_1\) has a map stage duration of \(J_1^M = 10\)s and the reduce stage duration of \(J_1^R = 1\)s.
- Job \(J_2\) has a map stage duration of \(J_2^M = 1\)s and the reduce stage duration of \(J_2^R = 10\)s.

There are two possible executions shown in Figure 3:

- \(J_1\) is followed by \(J_2\) shown in Figure 3(a). The reduce stage of \(J_1\) overlaps with the map stage of \(J_2\) leading to overlap of only 1s. The total completion time of processing two jobs is \(10+1+10+1 = 22\)s.
- \(J_2\) is followed by \(J_1\) shown in Figure 3(b). The reduce stage of \(J_2\) overlaps with the map stage of \(J_1\) leading to a much better pipelined execution and a larger overlap of 10s. The total makespan is \(1+10+1+1 = 12\)s.

\(^4\)The shuffle stage is included in the reduce task. For a first shuffle phase that overlaps with the entire map phase, only a complementary (non-overlapping) portion is included in the reduce task.

There is a significant difference in the jobs makespan (75% in the example above) depending on the execution order of the jobs.

Since in this work we consider a problem of minimizing the cost of rented Hadoop cluster and the jobs completion time directly impacts this cost, we aim to generate the job executions order that minimizes the jobs’ makespan. Thus, let \(\mathcal{J} = \{J_1, J_2, \ldots, J_n\}\) be a set of \(n\) MapReduce jobs with no data dependencies between them. For minimizing the makespan of a given set of MapReduce jobs, we apply the classic Johnson’s algorithm [6] that was proposed for building an optimal job schedule in two-stage production systems. Johnson’s schedule can be efficiently applied to minimizing the makespan of MapReduce jobs as it was shown in [15].

Let us consider a collection \(\mathcal{J}\) of \(n\) jobs, where each job \(J_i\) is represented by the pair \((m_i, r_i)\) of map and reduce stage durations respectively. Note, we can estimates \(m_i\) and \(r_i\) by using bounds-based model. Let us augment each job \(J_i = (m_i, r_i)\) with an attribute \(D_i\) that is defined as follows:

\[
D_i = \begin{cases} 
(m_i, m) & \text{if } \min(m_i, r_i) = m_i, \\
(r_i, r) & \text{otherwise.}
\end{cases}
\]

The first argument in \(D_i\) is called the stage duration and denoted as \(D_i^M\). The second argument is called the stage type (map or reduce) and denoted as \(D_i^R\).

Algorithm 1 shows how an optimal schedule can be constructed using Johnson’s algorithm.

\[ \text{Algorithm 1 Johnson’s Algorithm} \]

\[ \text{Input: A set } \mathcal{J} \text{ of } n \text{ MapReduce jobs. } D_i \text{ is the attribute of job } J_i \text{ as defined above.} \]

\[ \text{Output: Schedule } \sigma \text{ (order of jobs execution.)} \]

1: Sort the original set \(\mathcal{J}\) of jobs into the ordered list \(L\) using their stage duration attribute \(D_i^M\).
2: \(head \leftarrow 1\), \(tail \leftarrow n\).
3: for each job \(J_i\) in \(L\) do
4: \(\text{if } D_i^M = m \text{ then} \)
5: \(// \text{Put job } J_i \text{ from the front} \)
6: \(\sigma_{head} \leftarrow J_i, head \leftarrow head + 1\)
7: \(\text{else} \)
8: \(// \text{Put job } J_i \text{ from the end} \)
9: \(\sigma_{tail} \leftarrow J_i, tail \leftarrow tail - 1\)
10: \(\text{end if} \)
11: \(\text{end for} \)

First, we sort all the \(n\) jobs from the original set \(\mathcal{J}\) in the ordered list \(L\) in such a way that job \(J_i\) precedes job \(J_{i+1}\) if and only if \(\min(m_i, r_i) \leq \min(m_{i+1}, r_{i+1})\). In other words, we sort the jobs using the stage duration attribute \(D_i^M\) in \(D_i\) (it represents the smallest duration of the two stages). Then the algorithm works by taking jobs from list \(L\) and placing them into the schedule \(\sigma\) from the both ends (head and tail) and proceeding towards the middle. If the stage type in \(D_i\) is \(m\), i.e., represents the map stage, then the job \(J_i\) is placed from the head of the schedule, otherwise from the tail. The complex-
Our solution is based on a simulation framework: in a brute-force manner, it searches through the entire solution space by exhaustively enumerating all possible candidates for the solution and checking whether each candidate satisfies the required problem’s statement. Figure 5 shows the diagram for the framework execution in decision making process per selected platform type. For example, if the platform forms of interest are small, medium, and large EC2 VM instances then the framework will generate three trade-off curves. For each platform and a given Hadoop cluster size, the Job Scheduler component generates the optimized MapReduce job schedule. Then the jobs’ makespan is obtained by replaying the job traces in the simulator according to the generated schedule. After that the size of the cluster is increased by one instance (in the cloud environment, it is equivalent to adding a node to a Hadoop cluster) and the iteration is repeated: a new job schedule is generated and its makespan is evaluated with the simulator, etc. We have a choice of stop conditions for iterations: either a user can set a range of values for the cluster size or at some point, the increased cluster size does not improve the achievable makespan. The latter condition typically happens when the Hadoop cluster is large enough to accommodate all the jobs to be executed concurrently, and therefore, the increased cluster size cannot improve the jobs makespan.

Assume that a set of given jobs should be processed within deadline $D$, and let $Price_{type}^i$ be the price of a type $i$ VM instance in the cluster configuration. Then a customer with budget $B$ can rent $N_{type}^{i_{max}}$ of VM instances of a given type:

$$N_{type}^{i_{max}} = \frac{B}{(D \cdot Price_{type}^i)}$$

(1) Algorithm 2 shows the pseudo code to determine the size of a cluster which is based on the type VM instances for processing $W$ with deadline $D$ and which results in the minimal monetary cost.

The algorithm iterates through the increasing number of instances for a Hadoop cluster. It simulates the completion time of workload $W$ processed with Johnson’s schedule on a given size cluster and computes the corresponding cost (lines 2-6). Note, that $k$ defines the number of worker nodes in the cluster. The overall Hadoop cluster size is $k + 1$ nodes (we add a dedicated node for Job Tracker and Name Node, which is included in the cost). The $min\_cost_{type}^{i_{max}}$ keeps track of a minimal cost so far (lines 7-8) for a Hadoop cluster which can process $W$ within deadline $D$.

One of the reader questions might be why do we continue iterating through the increasing number of instances once we found a solution which can process $W$ within deadline $D$? At a glance, when we keep increasing the Hadoop cluster – the solution becomes more expensive cost-wise. In reality, it is not always true: where could be a situation when a few additional nodes and a different Johnson schedule might significantly improve the makespan of a given workload, and as a result the cost of this larger cluster is smaller (due

3. **HOmogeneous CLUSTER SOLUTION**

In this work, we consider the following two problems for the homogeneous cluster case.

- For a given workload defined as a set of jobs $W = \{J_1, J_2, \ldots, J_n\}$ to be processed within deadline $D$, determine a Hadoop cluster configuration (i.e., the number and types of VM instances, and the job schedule) for processing these jobs within a given deadline while minimizing the monetary cost for rented infrastructure.

- For a given workload $W = \{J_1, J_2, \ldots, J_n\}$ and a given customer budget $B$, determine a Hadoop cluster configuration (i.e., the number and types of VM instances, and the job schedule) for processing these jobs within an allocated monetary cost for rented infrastructure while minimizing the jobs’ processing time.

The basic blocks of the simulator are the following:

1. **Trace Generator** – a module that generates a replayable workload trace. This trace is generated either from the detailed job profile (provided by the Job Profiler) or by feeding the distribution parameters for generating the synthetic trace (this path is taken when we need to generate the job execution traces from the sampled executions on the smaller datasets).

2. **Simulator Engine** – a discrete event simulator that takes the cluster configuration information and accurately emulates the Hadoop job master decisions for map/reduce slot allocations across multiple jobs.

3. **Scheduling policy** – a scheduling module that dictates the jobs’ ordering and the amount of allocated resources to different jobs over time.

Thus, for a given Hadoop cluster size, given set of jobs, and generated Johnson’s schedule, the simulator can accurately estimate the jobs’ completion time (makespan) by replaying the job traces accordingly to the generated schedule.
Algorithm 2 Provisioning solution for a homogeneous cluster to process \( W \) with deadline \( D \) while minimizing the cluster cost

Input:
- \( W = \{J_1, J_2, ..., J_n\} \) ← workload with traces and profiles for each job;
- \( \text{type} \) ← VM instance type, e.g., type ∈ \{small, medium, large\};
- \( N_{\text{max}}^\text{type} \) ← the maximum number of instances to rent;
- \( \text{Price}^\text{type} \) ← unite price of a type VM instance;
- \( D \) ← a given time deadline for processing \( W \).

Output:
- \( N^\text{type} \) ← an optimized number of VM type instances for a cluster;
- \( \min \text{cost}^\text{type} \) ← the minimal monetary cost for processing \( W \).

1: \( \min \text{cost}^\text{type} \leftarrow \infty \)
2: for \( k \leftarrow 1 \) to \( N_{\text{max}}^\text{type} \) do
3: // Simulate completion time for processing workload \( W \) with \( k \) VMs
4: \( \text{Cur}_\text{CT} = \text{Simulate}(\text{type}, k, W) \)
5: // Calculate the corresponding monetary cost
6: \( \text{cost} = \text{Price}^\text{type} \times (k+1) \times \text{Cur}_\text{CT} \)
7: if \( \text{Cur}_\text{CT} \leq D \) & \( \text{cost} < \min \text{cost}^\text{type} \) then
8: \( \min \text{cost}^\text{type} \leftarrow \text{cost} \), \( N^\text{type} \leftarrow k \)
9: end if
10: end for

4. GENERAL CASE WITH NODE FAILURES

The application performance of a customer workload may vary significantly on different platforms. Seemingly equivalent platform choices for a Hadoop cluster in the Cloud might result in a different application performance and a different provisioning cost, which leads to the problem of an optimized platform choice that can be obtained for the same budget. Moreover, there could be an additional issue for the user to consider: the impact of node failures on the choice of the underlying platform for a Hadoop cluster. Hadoop is designed to support fault-tolerance, i.e., it finishes job processing even in case with node failures. It uses the remaining resources for restarting and recomputing failed tasks. Let us consider a motivating example described in Section 1, where a user may deploy three different clusters with different types of VM instances for the same budget:

- 40 small VMs, each configured with 1 map and 1 reduce slot;
- 20 medium VMs, each configured with 2 map and 2 reduce slots, and
- 10 large VMs, each configured with 4 map and 4 reduce slots.

Now, let us see how a node failure may impact cluster performance when Hadoop nodes are based on different VM types. If a Hadoop cluster is based on 40 small instances then a single node failure leads to a loss of 2.5% of the overall resources and only limited number of map and reduce tasks might be impacted. While in the case of a large instance, a single node failure leads to a loss of 10% of the overall resources and a much higher number of map and reduce tasks might be impacted.

For a business-critical, production workload \( W \), a user may consider the generalized service level objectives (SLOs) that include two separate conditions:

- a desirable completion time \( D \) for the entire set of jobs in the workload \( W \) under normal conditions;
- an acceptable degraded completion time \( D_{\text{deg}} \) for processing \( W \) in case of 1-node failure.

So, the problem is to determine a Hadoop cluster configuration (i.e., the number and types of VM instances, and the job schedule) for processing workload \( W \) with the makespan target \( D \) while minimizing the cost, such that the chosen solution also supports a degraded makespan \( D_{\text{deg}} \) in case of 1-node failure during the jobs processing.

The approach, proposed in the previous Section 3, can be generalized for the case with node failures. Figure 6 shows the extended diagram for the framework execution and decision making process per selected platform type with node failures. For example, if the platforms of interest are small, medium, and large EC2 VM instances then the framework will generate three different off sets. For each platform and a given Hadoop cluster size \( N \), the Job Scheduler component generates an optimized MapReduce job schedule, based on Johnson’s algorithm. Then the jobs’ makespan (in the normal mode) is obtained by replaying the job traces in the simulator according to the generated schedule. In parallel (see, the lower branch in Figure 6, that represents a case of 1-node failure), the jobs’ makespan is obtained by replaying the job traces according to the same generated job schedule in the decreased cluster size \( N - 1 \). After both branches are finished, the size of the cluster is increased by one instance (in the cloud environment, it is equivalent to adding a node to a Hadoop cluster) and the iteration is repeated: a new job schedule is generated and its makespan is evaluated with the simulator for both modes: normal and 1-node failure, etc.
The cluster size (for each instance type) is selected based on validity of both SLOs conditions: for normal execution to satisfy $D$ and in case of 1-node failure to support a degraded makespan $D_{\text{deg}}$. Algorithm 4 shows the pseudo-code to determine the size of a cluster which is based on the type VM instances for processing $W$ with generalized SLOs and that results in the minimal monetary cost.

**Algorithm 4** Provisioning solution for a homogeneous cluster to process $W$ with a deadline $D$ and with a degraded deadline $D_{\text{deg}}$ in case of 1-node failure while minimizing the cluster cost

The algorithm iterates through the increasing number of instances for a Hadoop cluster. It simulates the completion time of workload $W$ processed with Johnson’s schedule on a cluster of a given size $k$. Note, that the same job schedule is used for processing $W$ in case of a node failure, i.e., on a cluster of size $k-1$.

The overall Hadoop cluster size is $k+1$ nodes ($k$ defines the number of worker nodes in the cluster, and we add a dedicated node for Job Tracker and Name Node, which is included in the cost). The $\text{min\_cost}\_\text{type}$ keeps track of a minimal cost so far (lines 7-8) for a Hadoop cluster which can process $W$ within deadline $D$ under normal conditions and within deadline $D_{\text{deg}}$ in case of 1-node failure.

---

5. **HETEROGENEOUS SOLUTION**

In Section 1, we discussed a motivating example by analyzing TeraSort and KMeans performance on Hadoop clusters formed with different EC2 instances, and observing that these applications benefit from different types of VMs as their preferred choice. Therefore, a single homogeneous cluster might not always be the best choice for a workload mix with different applications, and a heterogeneous solution might offer a better cost/performance outcome.

However, a single (individual) application preference choice often depends on the size of a Hadoop cluster and given performance goals. Continuing the motivating example from Section 1, Figure 7 shows the trade-off curves for three representative applications TeraSort, Kmeans, and AdjList obtained as a result of exhaustive simulation of application completion times on different size Hadoop clusters. The Y-axis represents the job completion time while the X-axis shows the corresponding monetary cost. Each figure shows three curves for application processing by a homogeneous Hadoop cluster based on small, medium, and large VM instances respectively.

First of all, the same application can result in different completion times when being processed on the same platform at the same cost. This reflects an interesting phenomenon of “pay-per-use” model. There are situations when a cluster of size $N$ processes a job in $T$ time units, while a cluster of size $2 \cdot N$ may process the same job in $T/2$ time units. Interestingly, these two different size clusters have the same cost, and if the purpose is meeting deadline $D$ where $T \leq D$ then both clusters meet the performance objective.

Second, we can see an orthogonal observation: in many cases, the same completion time can be achieved at a different cost (on the same platform type). Typically, this corresponds to the case when an increased size Hadoop cluster does not further improve the job processing time.

Finally, according to Figure 7, we can see that for TeraSort, the small instances results in the best choice, while for Kmeans the large instances represent the most cost-efficient platform. However, the optimal choice for AdjList is not very clear, it depends on the deadline requirements, and the trade-off curves are much closer to each other than for TeraSort and Kmeans.

Another important point is that the cost savings vary across different applications, e.g., the execution of Kmeans on large VM instances leads to higher cost savings than the execution of TeraSort on small VMs. Thus, if we would like to partition a given workload $W = \{J_1, J_2, ..., J_n\}$ into two groups of applications each to be executed by a Hadoop cluster based on different type VM instances,
we need to be able to rank (order) these application with respect to their preference “strength” between two considered platforms.

In this work, we consider a heterogeneous solution that consists of two homogeneous Hadoop sub-clusters deployed with different type VM instances. As an example, we consider a heterogeneous solution formed by small (S) and large (L) VM instances. To measure the “strength” of application preference between two different VM types we introduce an application preference score \( P_{\text{Score}}^{S,L} \) defined as a difference between the normalized costs of simulated cost-performance curves (such as shown in Figure 7):

\[
P_{\text{Score}}^{S,L} = \frac{\sum_{1 \leq i \leq N_{\text{max}}}^{} \text{Cost}_i^S}{N_{\text{max}}} - \frac{\sum_{1 \leq i \leq N_{\text{max}}}^{} \text{Cost}_i^L}{N_{\text{max}}}
\]

where \( N_{\text{max}}^S \) and \( N_{\text{max}}^L \) are defined by Eq. 1 for Hadoop clusters with small and large VM type instances respectively.

The value of \( P_{\text{Score}}^{S,L} \) indicates the possible impact on the provisioning cost, i.e., a large negative (positive) value indicates a stronger preference of small (large) VM instances, while values closer to 0 reflect less sensitivity to the platform choice.

For optimized heterogeneous solution, we need to determine the following parameters:

- The number of instances for each sub-cluster (i.e., the number of worker nodes plus a dedicated node to host JobTracker and Name Node for each sub-cluster).

- The subset of applications to be executed on each cluster.

Algorithm 5 shows the pseudo code of our heterogeneous solution. For a presentation simplicity, we show the code for a heterogeneous solution with small and large VM instances.

First, we sort the jobs in the ascending order according to their preference ranking \( P_{\text{Score}}^{S,L} \). Thus the jobs in the beginning of the list have a performance preference for executing on the small instances. Then we split the ordered job list into two subsets: first one to be executed on the cluster with small instances and the other one to be executed on the cluster with large instances (lines 4-5). For each group, we use Algorithm 2 for homogeneous cluster provisioning to determine the optimized size of each sub-cluster for processing the assigned workload with a deadline \( \bar{D} \) that leads to the minimal monetary cost (lines 6-7). We consider all possible splits by iterating through the split point from 1 to the total number of jobs \( N \) and use a variable \( \text{min\_cost}^{S+L} \) to keep track of the found minimal total cost, i.e, the sum of costs from both sub-clusters (lines 9-12).

\[\text{min\_cost}^{S+L} \leftarrow \infty\]

\[\text{if } \text{total\_cost} < \text{min\_cost}^{S+L} \text{ then}\]

\[\text{W}^S \leftarrow \text{Jobs}^S, \text{W}^L \leftarrow \text{Jobs}^L\]

\[\text{end if}\]

6. EVALUATION

In this section, we describe the experimental testbeds and MapReduce workloads used in our study. We analyze the application performance and the job profiles when these applications are executed on different platforms of choice, e.g., small, medium, and large Amazon EC2 instances. The study aims to evaluate the effectiveness of the proposed algorithms for selecting the optimized platform for a Hadoop cluster and compare the outcomes for different workloads.

6.1 Experimental testbeds and workloads

In our experiments, we use the Amazon EC2 platform. It offers different capacity Virtual Machines (VMs) for deployment at different price. Table 1 provides descriptions of VM instance types used in our experiments. As it shows, the compute and memory capacity of a medium VM instance (m1.medium) is doubled compared to a small VM instance (m1.small) and similarly, a large VM instance (m1.large) has a doubled capacity compared to the medium VM. These differences are similarly reflected in pricing. We deployed Hadoop clusters that are configured with different number of map and reduce slots per different type VM instances (according to the...
capacity) as shown in Table 1. Each VM instance is deployed with 100GB of Elastic Block Storage (EBS). We use Hadoop 1.0.0 in all the experiments. The file system blocksize is set to 64MB and the replication level is set to 3.

Table 1: EC2 Testbed description.

In the performance study, we use a set of 13 applications released by the Tarazu project [2]. Table 2 provides a high-level summary of the applications with the corresponding job settings (e.g., the number of map/reduce tasks). Applications 1, 8, and 9 process synthetically generated data. Applications 2 to 7 use the Wikipedia articles dataset as input. Applications 10 to 13 use the Netflix movie ratings dataset. These applications perform very different data manipulations, which result in different resource requirements. To provide some additional insights in the amounts of data flowing through the MapReduce processing pipeline, we also show the overall size of the input data, intermediate data (i.e., data generated between map and reduce stages), and the output data (i.e., the data written by the reduce stage).

Table 2: Application characteristics.

6.2 Application performance analysis

We execute the set of 13 applications shown in Table 2 on three Hadoop clusters8 deployed with different types of EC2 VM instances (they can be obtained for the same price per time unit): i) 40 small VMs, ii) 20 medium VMs, and iii) 10 large VM instances. We configure these Hadoop clusters according to their nodes capacity as shown in Table 1, with 1 additional instance deployed as the NameNode and JobTracker.

These experiments pursue the following goals: i) to demonstrate the performance impact of executing these applications on the Hadoop clusters deployed with different EC2 instances; and 2) to collect the detailed job profiles for creating the job traces used for replay by the simulator and trade-off analysis in determining the optimal platform choice.

Figure 8 (a) presents the completion times (CT) of 13 applications executed on the three different EC2-based clusters. The results show that the platform choice may significantly impact the application processing time. Note, we break the Y-axis as KMeans and Classification executions take much longer time to finish compared to other applications. Figure 8 (b) shows the normalized results with respect to the execution time of the same job on the Hadoop cluster formed with small VM instances. For 7 out 13 applications, the Hadoop cluster formed with small instances leads to the best completion time (and the smallest cost). However, for the CPU-intensive applications such as Classification and KMeans, the Hadoop cluster formed with large instances shows better performance.

Tables 3-5 summarize the job profiles collected for these applications. They show the average and maximum durations for the map, shuffle and reduce phase processing as well as the standard deviation for these phases. The analysis of the job profiles show that the shuffle phase durations of the Hadoop cluster formed with small instances are much longer compared to the clusters formed with large instances. The reason is that the Amazon EC2 instance scaling is done with respect to the CPU and RAM capacity, while the storage and network bandwidth is only fractionally improved. As we configure a higher number of slots on large instances, it increases the I/O and network contention among the tasks running on the same instance, and it leads to significantly increased durations of the shuffle phase. At the same time, the map task durations of most applications executed on the Hadoop cluster with large instances are significantly improved, e.g., the map task durations of Classification and KMeans applications improved almost three times.

The presented analysis of job profiles show that a platform choice for a Hadoop cluster may have a significant impact on the application performance. This analysis further demonstrates the importance of an effective mechanism and algorithms for helping to make the right provisioning decisions based on the workload characteristics.

6.3 Comparison of homogeneous and heterogeneous solutions

In this section, we use workloads created from the applications shown in Table 2 for comparing the results of both homogeneous and heterogeneous provisioning solutions. The following Table 6 provides an additional application characterization by reflecting the application preference score $PScore^{S,L}$. A positive value (e.g., Kmeans, Classification) indicates that the application is more cost-efficient on large VMs, while a negative value (e.g., TeraSort, WordCount) means that the application favors small VM instances. The absolute score value is indicative of the preference “strength”. When the preference score is close to 0 (e.g., AdjList), it means that the application does not have a clear preference between the instance types.

</table>
Intuitively, there is a different number of applications that strongly favor large VM instances in each workload: \( W_1 \) has both KMeans and Classification, workload \( W_2 \) does not have any of them, and workload \( W_3 \) has only Classification.

Figure 9 shows the simulated cost/performance trade-off curves for three workloads executed on both homogeneous and heterogeneous Hadoop cluster(s). These trade-off curves are results of the brute-force algorithm design, it searches through the entire solution space by exhaustively enumerating all possible candidates for the solution. So, these trade-off curves do show all the solutions that our algorithms iterate through. For homogeneous provisioning, we show the three trade-off curves of Algorithm 2 for Hadoop clusters based on small, medium and large VM instances respectively.

Figure 9 (a) shows that workload \( W_1 \) is more cost-efficient when executed on the Hadoop cluster with large VMs (among the homogeneous clusters). Such results can be expected because \( W_1 \) contains both KMeans and Classification that have very strong preference towards large VM instances (see their high positive PScore\(^S,L\)). In comparison, \( W_2 \) contains applications that mostly favor the small VM instances, and as a result, the most efficient trade-off curve belongs to a Hadoop cluster based on the small VM instances. Finally, \( W_3 \) represents a mixed case: it has Classification application that strongly favors large VM instances while most of the remaining applications prefer small VM instances. Figure 9(c) shows that a choice of the best homogeneous platform depends on the workload performance objectives (i.e., deadline \( D \)).

The yellow dots in Figure 9 represent the completion time and monetary cost when we exploit a heterogeneous provisioning case with Algorithm 5. Each point corresponds to a workload split into two subsets that are executed on the Hadoop cluster formed with small and large VM instances respectively. This is why instead of the explicit trade-off curves as in the homogeneous cluster case, the simulation results for the heterogeneous case look much more scattered across the space.

To evaluate the efficiency of our provisioning algorithms, we consider different performance objectives for each workload:
- \( D = 20000 \) seconds for workload \( W_1 \);
- \( D = 10000 \) seconds for workload \( W_2 \);
- \( D = 15000 \) seconds for workload \( W_3 \).

Tables 7-9 present the provisioning results for each workload with homogeneous and heterogeneous Hadoop clusters that have minimal monetary costs while meeting the given workload deadlines.

Among the homogeneous Hadoop clusters for \( W_1 \), the cluster with large VM instances has the lowest monetary cost of $32.86, that provides 41% cost saving compared to a cluster with small VMs.

By contrast, for workload \( W_2 \), the homogeneous Hadoop cluster with small VMs provides the lowest cost of $10.68, that provides 68% cost saving compared to a cluster with large VM instances.

For \( W_3 \), all the three homogeneous solutions lead to a similar minimal cost, and the Hadoop cluster based on medium VMs has a slightly better cost than the other two alternatives.

Intuitively, these performance results are expected from the trade-off curves for three workloads shown in Figure 9.

The best heterogeneous solution for each workload is shown in the last row in Tables 7-9. For \( W_1 \), the minimal cost of the heterogeneous solution is $24.21 which is 26% improvement compared to the minimal cost of the homogeneous solution based on the large VM instances. In this heterogeneous solution, the applications SelfJoin, WordCount, ImvIndex are executed on the cluster with small VMs and applications Classif, Kmeans, TermVector, Adjlist, HistMovies, HistRAting, Grep, TeraSort, SeqCount, RankImvInd are executed on the cluster with large VM instances.

The cost benefits of the heterogeneous solution is even more significant for \( W_3 \) as shown in Table 9. The minimal cost for heterogeneous cluster is $18.0 compared with the minimal cost for a homogeneous provision of $31.05, it leads to cost savings of 42% compared to the minimal cost of the homogeneous solution. In this heterogeneous solution, the applications HistMovies, HistRAting, Grep, TeraSort, SeqCount, RankImvInd, SelfJoin, WordCount, ImvIndex are executed on the cluster with small VMs and applications Classif.
TermVector, Adjlist are executed on the cluster with large VMs.

However, for workload W2, the heterogeneous solution does not provide additional cost benefits as shown in Table 8. One important reason is that for a heterogeneous solution, we need to maintain additional nodes deployed as JobTracker and NameNode for each sub-cluster. This increases the total provisioning cost compared to the homogeneous solution which only requires a single additional node for the entire cluster. The workload properties also play an important role here. As W2 workload does not have any applications that have “strong” preference for large VM instances, the introduction of a special sub-cluster with large VM instances is not justified.

### 6.4 Impact of node failures on the cluster platform’s selection

In this section, we show how the cluster platform’s selection may be impacted when a user additionally considers a possibility of a node failure(s), and he/she is interested in achieving the generalized service level objectives (SLOs) which include two different performance goals for workload execution under a normal scenario and a case with 1-node failure:

- a desirable completion time \(D\) for the entire set of jobs in the workload \(W\) under normal conditions;
- an acceptable degraded completion time \(D_{deg}\) for processing \(W\) in case of 1-node failure.

Intuitively, a node failure in the Hadoop cluster formed with small EC2 instances may have smaller impact than a node failure in the cluster formed with large EC2 instances.

Let us demonstrate the decision making process for two applications from our set (see Table 2): TermVector and AdjList.

The completion time versus cost curves for applications TermVector and AdjList are shown in Figures 10 and 7 (c) respectively.

![Figure 10: Performance versus cost trade-offs for TermVector](image)

From these figures and the preference score \(P_{Score}^{S,L}\) shown in Table 6, we can see that TermVector slightly favors large VM instances, while AdjList is practically neutral to the choice of small, medium, or large EC2 instances.

For these two applications, we apply our approach for selecting the underlying platform (a choice between small, medium, and large EC2 instances) to achieve the following performance objectives:

- **TermVector**:
  - \(D = 2900\) seconds (regular case, no node failures);
  - \(D_{deg} = 2930\) seconds (in case of 1-node failure).

- **AdjList**:
  - \(D = 1940\) seconds (regular case, no node failures);
  - \(D_{deg} = 1945\) seconds (in case of 1-node failure).

Table 10 summarizes the cluster provisioning results for a regular case and a scenario with 1-node failure for TermVector. We use abbreviations \(CT_{req}\) and \(CT_{fail}\) to denote the completion time in regular and 1-node failure cases respectively. Table 10 shows that in a possible node failure, and aims to meet stringent performance objectives then the platform choice based on small VM instances is a better choice.

Table 11: AdjList: cluster provisioning results for a regular case and a scenario with 1-node failure.

In a regular case scenario, a Hadoop cluster with medium EC2 instances offers the best solution for AdjList. However, in the scenario with 1-node failure, the platform choice based on small VM instances is a better choice.

The achievable cost and performance advantages are more significant for workloads that require small-size Hadoop clusters for achieving their performance objectives. In large Hadoop clusters, a loss of 1-node results in a less pronounced performance impact.

### 6.5 Validation of the simulation results

To validate the accuracy of the simulation results, we chose workload W2 and select the makespan target of 20000 seconds. We use our simulation results (shown in Figure 9 (b)) and identify four closest points that represent the corresponding four solutions. The selected points correspond to simulated homogeneous Hadoop clusters with 28, 20, 24 nodes formed by small, medium, and large EC2 instances respectively, and a heterogeneous solution with two Hadoop sub-clusters based on 26 small nodes and 20 large nodes. We deployed the Hadoop clusters with the required number of instances and have executed workload W2 (with the corresponding Johnson job schedule) on the deployed clusters. Figure 11 shows the comparison between the simulated and the actual measured makespan (we repeated measurements 5 times).

![Figure 11: Validation of the simulation results](image)
Table 12 summarizes validation results shown in Figure 11.

The simulated results with small and large EC2 instances, as well as the heterogeneous solution show 2-8% error compared to measured results.

</tbody>
</table>

Table 13: CPU types used by different EC2 instances.

We can see a higher prediction error (17%) for medium instances. Partially, it is due to a higher variance in the job profile measurements collected on medium instances.

6.6 Discussion

Towards a better understanding of what causes the application performance to be so different when executed by Hadoop clusters based on different VM instances, Figure 12 shows a detailed analysis of the execution time breakdown for Terasort and Kmeans on the small, medium, and large EC2 instances (we use the same Hadoop cluster configurations as described in our motivating example in Section 1).

**Figure 12: Analysis of TeraSort and KMeans on different EC2 instances.**

Terasort performance is dominated by the shuffle phase. Moreover, the shuffle duration is increasing when executed by Hadoop based on on medium and large instances compared to the Hadoop execution based on the small EC2 instances. The significantly longer shuffle time leads to an increased overall job completion time as shown in Figure 12 (a). One explanation is that the increased size EC2 instances are provided with a scaled capacities of CPU and RAM, but not of the network bandwidth. As we configure more slots on the large EC2 instances, it increases amount of the I/O and network traffic (as well as the contention) per each VM, and this leads to the increased duration of the shuffle phase. On the contrary, for Kmeans shown in Figure 12 (b), the map stage duration dominates the application execution time, and the map phase execution is significantly improved when executed on large EC2 instances. This can be explained by checking the CPU models of the underlying server hardware used to host different types of EC2 instances.

Over a month, every day we have reserved 20 instances of small, medium, and large EC2 instances. We could not set up the heterogeneous solution, so we executed Hadoop on different VM instances. Therefore, we have 60 small, 60 medium, and 60 large EC2 instances. The data placement strategy: a faster nodes store larger amount of input data stored on slow nodes. It also proposes a load-balancing approach for reduce computation by assigning different amounts of reduce work according to the node capacity. Xie et al. [18] try improving the MapReduce performance through a heterogeneity-aware data placement strategy: a faster nodes store larger amount of input data. In this way, more tasks can be executed by faster nodes without a data transfer for the map execution. Polo et al. [9] show that some MapReduce applications can be accelerated by using special hardware. The authors design an adaptive Hadoop scheduler that assigns such jobs to the nodes with corresponding hardware.

Another group of related work is based on resource management that considers monetary cost and budget constraints. In [10], the authors provide a heuristic to optimize the number of machines for a bag of jobs while minimizing the overall completion time under a given budget. This work assumes the user does not have any knowledge about the job completion time. It starts with a single machine
and gradually adds more nodes to the cluster based on the average job completion time updated every time when a job is finished. In our approach, we use job profiles for optimizing the job schedule and provisioning the cluster.

In [17], the authors design a budget-driven scheduling algorithm for MapReduce applications in the heterogeneous cloud. They consider iterative MapReduce jobs that take multiple stages to complete, each stage contains a set of map or reduce tasks. The optimization goal is to select a machine from a fixed pool of heterogeneous machines for each task to minimize the job completion time or monetary cost. The proposed approach relies on a prior knowledge of the completion time and cost for a task \( i \) executed on a machine \( j \) in the candidate set. In our paper, we aim at minimizing the makespan of the set of jobs and design an ensemble of methods and tools to evaluate the job completion times as well as their makespan as a function of allocated resources. In [8], Kllapi et al. propose scheduling strategies to optimize performance/cost trade-offs for general data processing workflows in the Cloud. Different machines are modelled as containers with different CPU, memory, and network capacities. The computation workflow contains a set of nodes as operators and edges as data flows. The authors provide both greedy and local search algorithms to schedule operators on different containers so that the optimal performance (cost) is achieved without violating budget or deadline constraints. Compared to our profiling approach, they estimate the operator execution time using the CPU container requirements. This approach does not apply for estimating the durations of map/reduce tasks — their performance depends on multiple additional factors, e.g., the amount of RAM allocated to JVM, the I/O performance of the executing node, etc. The authors present only simulation results without validating the simulator accuracy.

8. CONCLUSION

In this work, we designed a novel simulation-based framework for evaluating both homogeneous and heterogeneous Hadoop solutions to enhance private and public cloud offerings with a cost-efficient, SLO-driven resource provisioning. We demonstrated that seemingly equivalent platform choices for a Hadoop cluster might result in a very different application performance, and thus lead to a different cost. Our case study with Amazon EC2 platform reveals that for different workloads an optimized platform choice may result in 45-68% cost savings for achieving the same performance objectives. In our future work, we plan to use a set of additional microbenchmarks to profile and compare generic phases of the MapReduce processing pipeline across Cloud offerings, e.g., comparing performance of the shuffle phase across different EC2 instances to predict the general performance impact of different platforms on the user workloads.
